MemoryDock

Open-source memory for AI agents | Concept overview

1. What we are creating

MemoryDock is a reusable memory layer intended to help Grace and future agents remember facts, past experiences and tested methods. It would assemble relevant information into a small working context for the task at hand.

2. One memory system, different agents

Planned HTTP, MCP and SDK interfaces would let compatible agents save and retrieve memories through the same contract. Each integration would provide its user, agent and project identity, configure scoped access, and connect memory calls to its workflow.

3. How memory would work

A graph of entities and relationships would connect semantic facts, episodic events and procedural methods to their original sources. Retrieval would combine keyword search, meaning-based search and limited graph traversal.

4. Keeping it accurate and responsive

MemoryDock would add or supersede facts, support deletion, track validity and sources, and merge duplicate derived records. Source events would enter recent context before background graph enrichment, with pending corrections respected during retrieval.

5. Open source and replaceable parts

The project is MIT-licensed so others can use, modify and contribute to it, while personal memories remain in private deployments. Replaceable memory backends would keep agent integrations independent of a specific database or vendor.

6. Current stage

MemoryDock is currently a research-stage repository: the engine and connectors are not implemented, and speed has not been benchmarked. Graphiti, Zep, Mem0 and a custom backend remain options under study.
